**Abstract**

We discuss to which extent, the initial energy density $\epsilon$ reached in a collision, is 1) a discriminating parameter for the appearance of the QCD phase transition and 2) if so, if it is the only discriminating parameter, or there is e.g. a critical volume above which this transition can occur. These questions are investigated by means of calculations of the $\epsilon$ dependence of a) hadron number densities (hep-ph/0004138, hep-ph/0010228), and b) of the temperature and the strangeness suppression factor $\lambda_s$ extrapolated to zero fugacities at the chemical freeze-out (hep-ph/0010247). We use experimental data of A+A, $e^+ + e^-$, $p+p$ and $p+\overline{p}$ collisions at $\sqrt{s}$=2.6 GeV to 1.8 TeV, including new RHIC data. The results are interpreted as mapping out the QCD phase transition boundary universally in A+A as well as in particle reactions, with $\epsilon_{init,critical} \sim 1$ GeV/fm$^3$ and $T_{freeze-out,critical}$=155 $\pm$ 20 MeV. Strangeness is enhanced over light quarks in the reactions going through the QGP phase, as compared to the ones which do not cross the boundary. However, no additional strangeness enhancement is observed in nucleus+nucleus collisions with respect to elementary collisions at the same ($\epsilon_{init}$, $\mu_b$, $\mu_s$).
